Abstract
Sommerville [10] and Davies [2] classified the spherical triangles that can tile the sphere in an edge-to-edge (“normal”) fashion. Relaxing this condition yields other triangles, which tile the sphere but have some tiles intersecting in partial edges. This paper determines which right spherical triangles within certain families can tile the sphere.

Keywords: spherical right triangle, monohedral tiling, non-normal, non-edge-to-edge, asymptotically right

AMS subject classification: 52C20

1 Introduction

A tiling is called *homohedral* if all tiles are congruent, and *normal* if two tiles that intersect do so in a single vertex or an entire edge. In 1923, D.M.Y. Sommerville [10] classified the normal homohedral tilings of the sphere with isosceles triangles, and those with scalene triangles in which the angles meeting at any one vertex are congruent. H.L. Davies [2] completed the classification of normal homohedral tilings by triangles in 1967 (apparently without knowledge of Sommerville's work), allowing any combination of angles at a vertex. (Coxeter[1] and Dawson[5] both erred in failing to note that Davies does include triangles - notably the half- and quarter-lune families - that Somerville did not consider.)

There are, of course, reasons why the normal tilings are of special interest; however, non-normal tilings do exist, including some [3, 4, 5] using tiles that cannot tile in a normal fashion. In [3] a complete classification of isosceles spherical triangles that tile the sphere was given. In [5] a special class of right triangles was considered, and shown to contain only one triangle that could tile the sphere.

This paper and its companion papers [6, 7, 8] continue the program of classifying the triangles that tile the sphere, by giving a complete classification of the right triangles with this property. Non-right triangles will be classified in future work.

2 Basic results and definitions

In this section we gather together some elementary definitions and basic results used later in the paper. We will represent the measure of the larger of the two non-right angles of the triangle by $\beta$ and that of the smaller by $\gamma$. The lengths of the edges opposite these angles will be $B$ and $C$ respectively, with $H$ as the length of the hypotenuse. (Note that it may be that $\beta > 90^\circ$ and $B > H$.) We will make frequent use of the well known result

$$90^\circ < \beta + \gamma < 270^\circ, \quad \beta - \gamma < 90^\circ \quad (1)$$

We will denote the number of tiles by $N$; this is of course equal to $720^\circ / (\beta + \gamma - 90^\circ)$.

Let $\mathcal{V} = \{(a, b, c) \in \mathbb{Z}^3 : a\alpha + b\beta + c\gamma = 360^\circ, a, b, c \geq 0\}$. We call the triples $(a, b, c)$ the *vertex vectors* of the triangle and the equations *vertex equations*. The vertex vectors represent the possible (unordered) ways to surround a vertex with the available angles.

We call $\mathcal{V}$ itself the *vertex signature* of the triangle. For right triangles $\mathcal{V}$ is always nonempty, containing at least $(4, 0, 0)$. Any subset of $\mathcal{V}$ that is linearly independent over $\mathbb{Z}$ and generates $\mathcal{V}$ is called a *basis* for $\mathcal{V}$. All bases for $\mathcal{V}$ have the same number of elements; if bases for $\mathcal{V}$ have $n + 1$ elements we will define the *dimension* of $\mathcal{V}$, $\dim(\mathcal{V})$, to be $n$. An oblique triangle could in principle have $\mathcal{V} = \emptyset$ and $\dim(\mathcal{V}) = -1$; but such a triangle could not even tile the neighborhood of a vertex. The dimension of $\mathcal{V}$ may be less than the dimension.
of the lattice \( \{(a,b,c) \in \mathbb{Z}^3 : a\alpha + b\beta + c\gamma = 360^\circ \} \) that contains it, but it cannot be greater.

If a triangle can tile the sphere in a non-normal fashion, it must have one or more split vertices at which one or more edges ends at a point in the relative interior of another edge. The angles at such a split vertex must add to 180°, and two copies of this set of angles must give a vertex vector in which \( a, b, \) and \( c \) are all even. We shall call \((a, b, c)\) even and \((a, b, c)/2\) a split vector. We will call \((a, b, c)/2\) an \( \beta \) (resp. \( \gamma \)) split if \( b \) (resp. \( c \)) is nonzero. If both are nonzero we will call the split vector a \( \beta\gamma \) split.

It is easily seen that if \((3, a, b) \in \mathcal{V}\), then also \((0, 4a, 4b) \in \mathcal{V}\); and if \((2, a, b) \in \mathcal{V}\), then also \((0, 2a, 2b) \in \mathcal{V}\). A vertex vector with \( a = 0 \) or 1 will be called reduced. If \( \mathcal{V} \) contains a vector \((a, b, c)\) such that \((a, b, c)/2\) is a \( \beta \) split, a \( \gamma \) split, or a \( \beta\gamma \) split, then it must have a reduced vector corresponding to a split of the same type, which must necessarily have \( a = 0 \).

The following result was proved in [5]:

**Proposition 1**  The only right triangle that tiles the sphere, does not tile normally, and has no split vector apart from \((4, 0, 0)/2\) is the \((90^\circ, 108^\circ, 54^\circ)\) triangle.

In fact, this triangle tiles in exactly three distinct ways. One is illustrated in Figure 1; the others are obtained by rotating one of the equilateral triangles, composed of two tiles, that cover the polar regions.

![Figure 1: A tiling with the \((90^\circ, 108^\circ, 54^\circ)\) triangle](image)

This lets us prove:

**Proposition 2**  For any right triangle that tiles the sphere but does not tile normally, \( \dim(\mathcal{V}) = 2 \).
Proof: A right triangle with \( \dim(V) = 0 \) would have \((4,0,0)\) as its only vertex vector, which means that the neighborhood of a \( \beta \) or \( \gamma \) corner could not be covered. Moreover, the lattice \( \{(a,b,c) \in \mathbb{Z}^3 : a\alpha + b\beta + c\gamma = 360^\circ\} \) is at most two-dimensional; so \( \dim(V) \leq 2 \).

If \( \dim(V) = 1 \), the other basis vector \( V_1 = (a_1, b_1, c_1) \) must have \( b_1 = c_1 \). If \( a_1 = 2, b_1 = c_1 \geq 2 \) or \( a_1 = 0, b_1 = c_1 \geq 4 \), we would have \( \beta + \gamma \leq 90^\circ \); and if \( a_1 = 0, b_1 = c_1 = 2 \) the triangle is of the form \((90^\circ, \theta, 180^\circ - \theta)\) and tiles normally. Thus, under our hypotheses, there is no second split, and the only such triangle that tiles but not in a normal fashion is (by the previous proposition) the \((90^\circ, 108^\circ, 54^\circ)\) triangle. However, this has \( V = \{(4,0,0), (1,2,1), (1,1,3), (1,0,5)\} \), and \( \dim(V) = 2 \).

\[ \text{Corollary 1} \quad \text{There are no continuous families of right triangles that tile the sphere but do not tile normally.} \]

Proof: As \( \dim(V) = 2 \), the system of equations

\[
\begin{align*}
4\alpha + 0\beta + 0\gamma &= 360^\circ \quad (2) \\
 a_1\alpha + b_1\beta + c_1\gamma &= 360^\circ \quad (3) \\
 a_2\alpha + b_2\beta + c_2\gamma &= 360^\circ \quad (4)
\end{align*}
\]

has a unique solution \((\alpha, \beta, \gamma)\) whose angles (in degrees) are rational. \( \blacksquare \)

Note: Both the requirement that the triangle be right, and the requirement that it allow no normal tiling of the sphere, are necessary. Consider the \((\frac{360^\circ}{n}, 180^\circ - \theta, \theta)\) triangles where \( n \) is, in the first case, odd, and, in the second case, equal to 4. In each case \( \dim(V) = 1 \) for almost every \( \theta \) and the family is continuous. We may also consider the triangles with \( \alpha + \beta + \gamma = 2\pi \); four of any such triangle tile the sphere, almost every such triangle has \( \dim(V) = 0 \), and they form a continuous two-parameter family.

2.1 The irrationality hypothesis

With a few well-known exceptions such as the isosceles triangles, and the half-equilateral triangles with angles \((90^\circ, \theta, \theta/2)\), it seems natural to conjecture that a spherical triangle with rational angles will always have irrational ratios of edge lengths. This “irrationality hypothesis” is probably not provable without a major advance in transcendence theory. However, for our purposes it will always suffice to rule out identities of the form \( pH + qB + rC = p'H + q'B + r'C \) where \( p, q, r, p', q', r' \) are positive and the sums are less than \( 360^\circ \). For any specified triangle for which the hypothesis holds, this can be done by testing a rather small number of possibilities, and without any great precision in the arithmetic. This will generally be done without comment.
**Note:** The possibility that some linear combination \( pA + qB + rC \) of edge lengths will have a rational measure in degrees is **not** ruled out, and in fact this is sometimes the case. For instance, the \((90^\circ, 60^\circ, 40^\circ)\) triangle has \( H + 2B + 2C = 180^\circ \).

**Note:** It will be seen below that, while normal tilings tend to have mirror symmetries, the symmetry groups of non-normal tilings are usually chiral. The irrationality hypothesis offers an explanation for this. Frequently there will only be one way (up to reversal) to fit triangles together along one side of an extended edge of a given length without obtaining an immediately impossible configuration. If the configuration on one side of an extended edge is the reflection in the edge of that on the other, the tiling will be locally normal. A non-normal tiling must have an extended edge where this does not happen: the configuration on one side must either be completely different from that on the other or must be its image under a \(180^\circ\) rotation about the center of the edge.

**Note:** It may be observed that all known tilings of the sphere with congruent triangles have an even number of elements. This is easily seen for normal tilings, as \(3N = 2E\) (where \(E\) is the number of edges.) The irrationality hypothesis, if true, would explain this observation in general.

A maximal arc of a great circle that is contained in the union of the edges will be called an **extended edge**. Each side of an extended edge is covered by a sequence of triangle edges; the sum of the edges on one side is equal to that on the other. In the absence of any rational dependencies between the sides, it follows that one of these sequences must be a rearrangement of the other, so that \(3N\) is again even.

In light of this, one might wonder whether in fact every triangle that tiles the sphere admits a tiling that is invariant under point inversion and thus corresponds to a tiling of the projective plane; however, while some tiles do admit such a tiling, others do not. For instance, it is shown below that the \((90^\circ, 75^\circ, 60^\circ)\) triangle admits, up to reflection, a unique tiling; and the symmetry group of that tiling is a Klein 4-group consisting of the identity and three \(180^\circ\) rotations.

### 2.2 Classification of \(\beta\) sources

It follows from Proposition 2 that the vertex signature of every triangle that tiles but does not do so in a normal fashion must contain at least one vector with \(b > a, c\) and at least one with \(c > a, b\). We will call such vectors \(\beta\) **sources** and \(\gamma\) **sources** respectively; and we may always choose them to be reduced. Henceforth, then, we will assume \(\mathcal{V}\) to have a basis consisting of three vectors \(V_0 = (4, 0, 0), V_1 = (a, b, c),\) and \(V_2 = (a', b', c')\), with \(a, a' < 2, b > c,\) and \(b' < c'\). (For some triangles, more than one basis satisfies these conditions; this need not concern us.)

The restrictions that \(\beta > \gamma\) and \(b > c\) leave us only finitely many possibilities for \(V_1\). In particular, if \(b + c > 7\), then \(360^\circ = b\beta + c\gamma > 4\beta + 4\gamma\) and \(\beta + \gamma < 90^\circ\).
which is impossible. Similarly, if $a = 1$ we must have $b + c \leq 5$. We can also rule out the vectors $(0, 2, 0)$, $(0, 1, 0)$, and $(1, 1, 0)$, all of which force $\beta \geq 180^\circ$.

We are left with 22 possibilities for $V_1$. We may divide them into three groups, depending on whether $\lim_{c' \to \infty} \beta$ is acute, right, or obtuse.

- The asymptotically acute $V_1$ are $(0, 7, 0)$, $(0, 6, 1)$, $(0, 6, 0)$, $(0, 5, 2)$, $(0, 5, 1)$, $(0, 5, 0)$, $(1, 5, 0)$, $(1, 4, 1)$, and $(1, 4, 0)$. As for large enough $c'$ these yield Euclidean or hyperbolic triangles, there are only finitely many vectors $V_2$ that can be used in combination with each of these.

- The asymptotically right $V_1$ are $(0, 4, 3)$, $(0, 4, 2)$, $(0, 4, 1)$, $(0, 4, 0)$, $(1, 3, 2)$, $(1, 3, 1)$, and $(1, 3, 0)$. Each of these vectors forms part of a basis for $V$ for infinitely many spherical triangles.

- The asymptotically obtuse $V_1$ are $(0, 3, 2)$, $(0, 3, 1)$, $(0, 3, 0)$, $(0, 2, 1)$, $(1, 2, 1)$, and $(1, 2, 0)$. For large enough $c'$ these yield triples of angles that do not satisfy the second angle inequality; so again there are only finitely many possible $V_2$ to consider.

In the remainder of this paper, we will classify the triangles that tile the sphere and have vertex signatures with asymptotically right $V_1$. One particularly lengthy subcase is dealt with in a companion paper [6]. A paper now in preparation will classify the right triangles that tile the sphere and have vertex signatures with asymptotically obtuse or acute $V_1$, completing the classification of right triangles that tile the sphere.

### 3 The main result

The main result of this paper is the following theorem, the proof of which will be deferred until the next section.

**Theorem 1** The right spherical triangles which have vertex signatures with asymptotically right $V_1$ are

1. $(90^\circ, 90^\circ, \frac{180^\circ}{n})$,
2. $(90^\circ, 60^\circ, 45^\circ)$,
3. $(90^\circ, 90^\circ - \frac{180^\circ}{n}, \frac{360^\circ}{n})$ for even $n \geq 4$,
4. $(90^\circ, 90^\circ - \frac{180^\circ}{n}, \frac{360^\circ}{n})$ for odd $n > 4$,
5. $(90^\circ, 75^\circ, 60^\circ)$,
6. $(90^\circ, 60^\circ, 40^\circ)$,
7. $(90^\circ, 75^\circ, 45^\circ)$, and
8. $(90^\circ, 78 \frac{3}{4}^\circ, 33 \frac{3}{4}^\circ)$. 

The first three of these tile normally, though they also admit non-normal tilings. The remaining five have only non-normal tilings.

We now examine the tiles listed above in more detail.

\textbf{i-iii) The three normal cases}

Both Sommerville and Davies included the \((90^\circ, 90^\circ, \frac{360^\circ}{n})\) and \((90^\circ, 60^\circ, 45^\circ)\) triangles in their lists; but Sommerville did not include the \((90^\circ, 90^\circ - \frac{180^\circ}{n}, \frac{360^\circ}{n})\) triangles, which are not isosceles and do not admit a tiling with all the angles equal at each vertex.

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{example_normal_tiles.png}
\caption{Examples of normal tilings}
\end{figure}

Sommerville and Davies give two normal tilings with the first family of triangles when \(n\) is even, and Davies gives a second normal tiling with the \((90^\circ, 60^\circ, 45^\circ)\) triangle. In each case these are obtained by “twisting” the tiling shown along a great circle composed of congruent edges, until vertices match up again. (For a clear account of these the reader is referred to Ueno and Agaoka [11].) There are also a large number of non-normal tilings with these triangles, which we shall not attempt to enumerate here; some of the possibilities are described in [3].

\textbf{iv) The \((90^\circ, 90^\circ - \frac{180^\circ}{n}, \frac{360^\circ}{n})\) quarterlunes \((n\ odd)\)}

When \(n\) is odd, there is no normal tiling with the \((90^\circ, 90^\circ - \frac{180^\circ}{n}, \frac{360^\circ}{n})\) triangle. However, there are tilings, in which the sphere is divided into \(n\) lunes with polar angle \(\frac{360^\circ}{n}\), each of which is subdivided into four \((90^\circ, 90^\circ - \frac{180^\circ}{n}, \frac{360^\circ}{n})\) triangles. This may be thought of as a further subdivision of the tiling with \(2n\) \((180^\circ - \frac{360^\circ}{n}, \frac{360^\circ}{n}, \frac{360^\circ}{n})\) triangles, given in in [3].

There are two ways to divide a lune into four triangles, mirror images of each other, and this choice may be made independently for each lune. When two adjacent dissections are mirror images, then the edges match up correctly.
on the common boundary; but with \( n \) odd, this cannot be done in every case. (However, it is interesting to note that a double cover of the sphere with 2\( n \) lunes can be tiled normally.) As shown in [3], there are approximately \( 2^{2n-2}/n \) essentially different tilings of this type.

The symmetry group depends on the choice of tiling; most tilings are completely asymmetric. We have \( V = \{(4, 0, 0), (2, 2, 1), (1, 1, \frac{2n}{2}), (0, 4, 2), (0, 0, n)\} \) in all cases (see section 5). It may be shown that no tiling with this tile can contain an entire great circle within the union of the edges; as the tile itself is asymmetric, no tiling can have a mirror symmetry. The largest possible symmetry group is thus the proper dihedral group of order 2\( n \).

We do not at present know whether there are other tilings with these triangles, as there are when \( n \) is even. Despite the existence of two vertex vectors not used in any of the known tilings, we conjecture that there are not.

\textbf{v) The \((90^\circ, 75^\circ, 60^\circ)\) triangle}

This triangle subdivides the \((150^\circ, 60^\circ, 60^\circ)\) triangle. It was shown in [3] that eight copies of the latter triangle tile the sphere; thus, sixteen \((90^\circ, 75^\circ, 60^\circ)\) triangles tile.

This tiling is unique up to mirror symmetry (Proposition 25). Its symmetry group is the Klein 4-group, represented by three 180\(^\circ\) rotations and the identity. (As this does not include the point inversion, we conclude that the \((90^\circ, 75^\circ, 60^\circ)\) triangle fails to tile the projective plane.) An interesting feature of this tiling (and the one it subdivides) is the long extended edge, of length 226.32\(^+\)\(^\circ\), visible in the figure.
vi) The \((90^\circ, 60^\circ, 40^\circ)\) triangle

This triangle tiles the sphere \((N = 72)\) in many ways. Two copies make one \((80^\circ, 60^\circ, 60^\circ)\) triangle, which was shown in [4] to tile the sphere in three distinct ways. Moreover, four copies yield the \((120^\circ, 60^\circ, 40^\circ)\) triangle, and six copies yield the \((140^\circ, 60^\circ, 40^\circ)\) triangle. Both of these tile as semilunes, giving tilings of the \(40^\circ\) and \(60^\circ\) lunes respectively (the latter already non-normal).

Figure 5: Some tilings with the \((90^\circ, 60^\circ, 40^\circ)\) triangle

Five copies yield the \((90^\circ, 100^\circ, 40^\circ)\) triangle, and seven yield the \((90^\circ, 120^\circ, 40^\circ)\) triangle. While neither of these tiles, either combines with the \((140^\circ, 60^\circ, 40^\circ)\), yielding the \((90^\circ, 140^\circ, 60^\circ)\) and \((90^\circ, 140^\circ, 80^\circ)\) triangle respectively; and com-
Bining all three gives a 90° lune (Figure 6), which does tile. It is interesting to note that this (unique; we leave this as an exercise to the reader!) tiling of the 90° lune has no internal symmetries; usually when a lune can be tiled it may be done in a centrally symmetric fashion.

![Figure 6: The unique tiling of the 90° lune with the (90°, 60°, 40°) triangle](image)

Furthermore, six tiles can also be assembled into an (80°, 80°, 80°) triangle, which, while it does not tile on its own, yields tilings in combination with three 100° lunes, each assembled out of one 40° and one 60° lune.

It seems probable that the most symmetric tiling is the one with nine 40° lunes, with a symmetry group of order 18 and 4 orbits; various other symmetries are possible, including completely asymmetric tilings. Some tilings (such as the one on the left in Figure 5) have central symmetry, so this triangle tiles the projective plane as well as the sphere.

A complete enumeration of the tilings with this tile remains an interesting open problem.

**vii: The (90°, 75°, 45°) triangle**

Eight copies of this triangle tile a 120° lune, in a rotationally symmetric fashion (Figure 7). There are exactly two distinct ways to fit three such lunes together, forming non-normal tilings with $N = 24$. Either the three lunes have the same handedness, in which case edges do not match on any of the three meridian boundaries and the symmetry group of the tiling is of order 6; or one lune has a different handedness than the other, edges match on two of the three meridians, and the symmetry group has order 2. It is conjectured that there are no other tilings.

A double cover of the sphere exists with 48 tiles in six lunes, alternating handedness; this double cover is normal.

**viii: The (90°, 78\(\frac{3}{4}\)°, 33\(\frac{3}{4}\)°) triangle**

This triangle is conjectured to tile uniquely (N=32) up to reflection (Figure 8). The symmetry group of the only known tiling is the Klein 4-group, represented
by three $180^\circ$ rotations and the identity. The tiles are partitioned into eight orbits under this symmetry group; this appears to be the largest possible number of orbits for a maximally symmetric tiling.

4 Proof of Theorem 1

The proof of Theorem 1 breaks up naturally into a sequence of propositions, dealing separately with each possible $V_1$. The nontrivial asymptotically right $V_1$ are $(0, 4, 3), (0, 4, 2), (0, 4, 1), (1, 3, 2)$, and $(1, 3, 1)$; there are also the trivial cases $(4, 0, 0)$ and $(0, 3, 1)$ for which the triangle is isosceles with two right angles. It is shown in [3] that these triangles tile the sphere precisely when the third
angle divides 360°; and in these cases there is always a normal tiling \([2, 10]\). For each remaining \(V_1\), we will begin by determining an exhaustive set of \(V_2\), and, for each of these, find the rest of \(V\). In some cases the lack of a split vector other than \((4, 0, 0)/2\) will then eliminate the triangle from consideration; in other cases we will need to examine the geometry explicitly.

4.1 The \((0, 4, 3)\) family

**Proposition 3** If a right triangle tiles the sphere and has \(V_1 = (0, 4, 3)\), then without loss of generality \(V_2 = (0, 0, c')\) or \((1, 1, c')\).

Proof: Consider any reduced \(\gamma\) source \(V = (a_V, b_V, c_V)\); by definition, \(a_V = 0\) or \(1\). If \(a_V = 1\) and \(1 < b_V\), we have \(c_V \geq 3\). Then \(W = 4V - 2(0, 4, 3) - (4, 0, 0)\) has \(a_W = 0\) and \(c_W > b_W > 0\) and is again a reduced \(\gamma\) source in \(V\). If \(a_V = 1\) and \(b_V = 0\), then \(W = 4V - (4, 0, 0)\) has \(a_W = b_W = 0\) and is also a reduced \(\gamma\) source in \(V\). Thus, without loss of generality, \(a_V = 0\) or \(a_V = 1\).

Now suppose \(a_V = 0\) and \(b_V > 0\). As \(V\) is a \(\gamma\) source, we must have \(b_V = 1, 2,\) or \(3\). If \(b_V = 2\), then \(W = 2V - (0, 4, 3)\) is a reduced \(\gamma\) source in \(V\) and has \(a_W = b_W = 0\). If \(b_V = 3\), then \(W = 4V - 3(0, 4, 3)\) is a reduced \(\gamma\) source in \(V\) with \(a_W = b_W = 0\). Finally, if \(b_V = 1\), we solve the system of equations

\[
\begin{pmatrix}
4 & 0 & 0 \\
0 & 4 & 3 \\
0 & 1 & c_V
\end{pmatrix}
\begin{pmatrix}
\alpha \\
\beta \\
\gamma
\end{pmatrix}
= 
\begin{pmatrix}
360° \\
360° \\
360°
\end{pmatrix}
\] (5)

to obtain

\[
\alpha = 90° \\
\beta = \left(\frac{360c_V - 1080}{4c_V - 3}\right)° \\
\gamma = \left(\frac{1080}{4c_V - 3}\right)°
\]

so that

\[
N = \frac{720°}{\alpha + \beta + \gamma - 180°} = \frac{32c_V}{3} - 8
\]

but this is only an integer when \(3|c_V\). As we have assumed that the triangle tiles, this must be the case; and \(W = \frac{4}{3}V - \frac{1}{3}(0, 4, 3)\) is a reduced \(\gamma\) source in \(V\) with \(a_W = b_W = 0\). \(\blacksquare\)

**Proposition 4** If a right triangle has \(V_1 = (0, 4, 3)\) and \(V_2 = (0, 0, c')\), then \(c' \geq 8\) and \(V\) consists of the vectors in the appropriate set below that have all...
components positive:

\[
\begin{cases}
\{(4,0,0),(0,4,3),(0,0,c'),(1,0,\frac{3c'}{4}),(2,0,\frac{c'}{4}),(3,0,0),(1,4,3-\frac{c'}{4})\} & \text{if } c' \equiv 0 \mod 4 \\
\{(4,0,0),(0,4,3),(0,0,c'),(0,2,\frac{c'-6}{4}),(2,1,\frac{c'+3}{4}),(2,3,\frac{6-c'}{4}),(0,6,\frac{9-c'}{4})\} & \text{if } c' \equiv 1 \mod 4 \\
\{(4,0,0),(0,4,3),(0,0,c'),(2,0,\frac{c'}{4}),(1,2,\frac{c'+6}{4})\} & \text{if } c' \equiv 2 \mod 4 \\
\{(4,0,0),(0,4,3),(0,0,c'),(0,1,\frac{5c'+3}{4}),(0,2,\frac{c'+3}{2}),(0,3,\frac{c'}{4}),(0,5,\frac{15-3c'}{4})\} & \text{if } c' \equiv 3 \mod 4.
\end{cases}
\]

(To be explicit, \((1,4,3-\frac{c'}{4})\) is present for \(c' = 8, 12\); \((2,3,\frac{3-c'}{4})\) and \((0,6,\frac{9-c'}{4})\) for \(c' = 9\); and \(0,5,\frac{15-3c'}{4}\) for \(c' = 11, 15\).)

Proof: (i) Solving, as above, for \(\beta\) and \(\gamma\), we have \(360c' - 1080 > 1080\) and \(c' \geq 8\).

(ii) The equation of the plane \(\Pi_V\) containing \(V\) is

\[4c = 4c' - c'a - (c' - 3)b.\]

We need to find the positive integer points on this plane. Substituting the lower bounds \(c' \geq 8\), \(c \geq 0\) into this, we obtain

\[8a + 5b < 32 \quad (7)\]

On the other hand, we note that, regardless of the value of \(c'\),

\[a + b \leq 4 \Rightarrow c > 0. \quad (8)\]

Reducing\((6)\) modulo 4, we obtain

\[(a + b)c' \equiv -b \mod 4. \quad (9)\]

The final step depends on the congruence class of \(c' \mod 4\).

\(c' \equiv 0: \) In this case, \((9)\) reduces to \(b \equiv 0\), and we have

\[(a,b) \in \{(0,0),(1,0),(2,0),(3,0),(4,0),(0,4),(1,4)\}\]

The first six of these pairs satisfy \((8)\) and thus give rise to solutions (as listed above) for all \(c'\); the last gives \(c \geq 0\) only for \(c' = 8, 12\).

\(c' \equiv 1: \) Now, \((9)\) reduces to \(a \equiv 2b\), and we have

\[(a,b) \in \{(0,0),(0,2),(0,4),(2,1),(4,0),(0,6),(2,3)\}\]

Again, the first five of these give rise to solutions for all \(c'\); the last gives \(c' \geq 0\) for \(c' = 9\) only.
\( c' \equiv 2 \): gives us \( 2a \equiv b \), and the only solutions are

\[(a, b) \in \{(0, 0), (0, 2), (0, 4), (1, 2), (2, 0), (4, 0)\}\]

All of these satisfy (8).

\( c' \equiv 3 \): makes \( a \equiv 0 \), and we have

\[(a, b) \in \{(0, 0), (0, 1), (0, 2), (0, 3), (0, 4), (4, 0), (0, 5)\}\]

All but the last of these satisfy (8); for \((0, 5)\) we get \( c \geq 0 \) only for \( c' = 11, 15 \).

Computing the various values of \( c \) completes the proof.

It was shown in [5] that the only right triangle to tile the sphere with no split vertex other than \((4, 0, 0)/2\) is the \((90^\circ, 108^\circ, 54^\circ)\) triangle (which has \( V_1 = (1, 2, 1) \)). Any other triangle is thus shown not to tile as soon as it is shown that it has no second split. In particular, the triangles considered above with \( c' \equiv 3 \) (mod 4) never tile. We also have the following:

**Proposition 5** No right triangle that has \( V_1 = (0, 4, 3) \) and \( V_2 = (1, 1, c') \) tiles the sphere.

Proof: The equation of of \( \Pi_V \) is

\[ 8c = 16c' - 12 - (4c' - 3)a - (4c' - 9)b. \] (10)

Computing modulo 8, we obtain \( a + 3b \equiv 4 \) (mod 8) when \( c' \) is odd, and \( 3a + b \equiv 4 \) (mod 8) when \( c' \) is even. Multiplying either of these congruences by 3 gives the other, so they have the same solutions.

The requirement that \( \beta > \gamma \) gives \( c' \geq 5 \), and substituting this and \( c \geq 0 \) into (10) gives us the inequality \( 14a + 8b \leq 56 \). But the only pairs \((a, b)\) that satisfy this inequality and the congruences are \((0, 4),(1, 1)\), and \((4, 0)\), so \( V \) never has any elements other than the given basis. Moreover, among these, only \((4, 0, 0)\) corresponds to a split, so by [5] none of these triangles tile the sphere.

**Proposition 6** The only right triangle that has \( V_1 = (0, 4, 3) \) and tiles the sphere is the \((90^\circ, 60^\circ, 40^\circ)\) triangle.

Proof: On the strength of the previous two propositions, we may assume that \( V_2 = (0, 0, c') \) with \( c' \geq 8 \) and \( c' \not\equiv 3 \) (mod 4). When \( c' = 9 \) we have the \((90^\circ, 60^\circ, 40^\circ)\) triangle.

If \( c' \equiv 1 \) (mod 4) and \( c' > 9 \), the only vertex vector corresponding to a split is \((0, 2, c'+3)\), in which \( \gamma \) angles outnumber \( \beta \) angles by at least 3; and the only \( \beta \) source is \((0, 4, 3)\). Let the vertex \( O \) be one such \( \beta \) source. At least one of the three triangles contributing a \( \gamma \) vertex to \( O \) must have its medium edge \( Oa \)
paired with a hypotenuse or short edge, not another medium edge.

If the other edge $Ob$ is a hypotenuse (Figure 9a,b), $b$ is necessarily a split vertex. If $Ob$ is short, (Figure 9c,d), there must again be an associated split vertex, on the extended edge $bc$. In every case, the split vertex has a surplus of at least three $\gamma$ angles. Examining the four configurations, we see that it is not possible for the identified split vertex to be related in any of these four ways to two $(0, 4, 3)$ vertices $O, O'$ unless certain relations hold among the edge lengths which are easily ruled out by numerical computation - for instance, in Figure 10, only a medium edge could fill the gap $bb'$ without a $\beta$ split; but it is easily verified that $3B \neq 2H$.

We conclude that every $(0, 4, 3)$ vertex is associated in a 1-1 fashion with a $(0, 2, 2n)/2$ split vertex; but this requires the number of $\gamma$ angles in the whole tiling to be greater than the number of $\beta$ angles, which is impossible. Thus, when $c' \equiv 1 \pmod{4}$ and $c' > 9$, the triangle does not tile.

If $c'$ is even, there are no $\beta$ splits, and unless $c' = 8$ or $12$, the only $\beta$ source is $(0, 4, 3)$. As above, every such vertex must have an unpaired medium edge. If this edge is covered by a hypotenuse $Ob$, this must be oriented as in Figure 9a, as the $\beta$ split in Figure 9b is impossible; and there is a $\gamma$ split at $b$. If it is covered by a short edge, there is a right-angle gap at $b$. In the absence of $\beta$ splits, this cannot be filled by another right angle (Figure 9c,d - numerical calculation rules out $B < 2C$ for any triangle in this family) and must therefore be a right-$\gamma$ split (Figure 9e). It is easily verified that no split vertex can be related as in Figure 9a or 9e to two $(0, 4, 3)$ vertices; so each $(0, 4, 3)$ is associated with a split vertex that it does not share with any other $(0, 4, 3)$, and between
them the number of $\gamma$ angles is again greater than the number of $\beta$ angles. Thus none of these triangles (including those with $c' = 8, 12$) tile using $(0, 4, 3)$ as the sole $\beta$ source.

The only remaining possibilities for tilings involve triangles with $c' = 8$ or $c' = 12$, using $(1, 4, 1)$ and $(1, 4, 0)$ respectively as $\beta$ sources. We shall show that these vertices, too, are necessarily associated with $\gamma$ splits.

When $c' = 8$, we obtain the $(90^\circ, 56.1^\circ, 45^\circ)$ triangle. Between them, the angles meeting at a $(1, 4, 1)$ vertex $O$ have five hypotenuses, at least one of which must be unpaired. The $\beta$ angle of the unpaired hypotenuse must be at $O$, or its other end would require a $\beta$ split. If we assume that the unpaired hypotenuse meets the short edge of the neighboring triangle, triangles 1, 2 and 3 of Figure 11 are forced in turn by avoiding $\beta$ splits. If it meets a long edge, one of Figure 11b,c is forced.

![Figure 11: Configurations near (1, 4, 1)](image)

In each of these three cases, the indicated two split vertices must exist. We must now consider whether at least one of these split vertices may form part of another configuration of the same type, another type from Figure 11, Figure 9a, or Figure 9e. Most of the 12 pairings are impossible unless the edge lengths satisfy simple equations that are easily ruled out, as in Figure 10.

The only three cases in which the designated split vertices can be shared are shown in Figure 12a (11b with another of the same type), Figure 12b (11c with another of the same type) and Figure 12c (11b with 9a). In each case, at least one right-angled gap bounded by medium edges or hypotenuses exists, and this cannot be filled by a right angle without requiring a $\beta$ split.

In figure 12a,b, then, two $(1, 4, 1)$ vertices share split vertices containing a total of eight $\gamma$ angles. In Figure 12c, one $(1, 4, 1)$ vertex and one $(0, 4, 3)$ vertex share split vertices containing six $\gamma$ angles. In every other case, a single $(1, 4, 1)$ vertex has sole custody of two split vertices with at least four $\gamma$ angles. In every case, these configurations require more $\gamma$ angles than $\beta$ angles; so the $(90^\circ, 56.1^\circ, 45^\circ)$ triangle does not tile.

We now consider the $(90^\circ, 67.5^\circ, 30^\circ)$ triangle, which has $c' = 12$. As shown above, it cannot tile without using vertices $(1, 4, 0)$ as $\beta$ sources. Any vertex of
this type has a single right angle, with an unpaired medium edge. This cannot meet the adjacent triangle (1, in Figure 12a) on a short edge, as avoiding $\beta$ splits gives us triangles 2,3,4, and 5, and then a $\beta$ split at $x$ cannot be avoided. If it meets a hypotenuse, the $\beta$ angle of the adjacent triangle must be at $O$, giving us 13b with two split vertices; and these are the only two possibilities.

![Figure 12: Two $\beta$ sources $O, O'$, sharing split vertices](image)

Figure 12: Two $\beta$ sources $O, O'$, sharing split vertices

Again, there are two special cases in which these $\gamma$ splits may be shared with another $\beta$ source. In Figure 13c, two $(1, 4, 0)$ vertices $O, O'$ share both their split vertices. The triangles 3,3’, are then forced; the right-angled gaps cannot be filled with right angles without a $\beta$ split; and so $O$ and $O'$ share twelve $\gamma$ angles. A similar argument shows that the $(1, 4, 0)$ and $(0, 4, 3)$ in Figure 13d share nine $\gamma$ angles. In every case, $\gamma$ angles outnumber $\beta$ angles, so that the triangle cannot tile. ■

![Figure 13: Configurations near $(1, 4, 0)$ vertices](image)

Figure 13: Configurations near $(1, 4, 0)$ vertices

4.2 The $(0, 4, 2)$ family

**Proposition 7** If a right triangle tiles the sphere and has $V_1 = (0, 4, 2)$ then without loss of generality $V_2 = (0, 0, c')$. Conversely, every triangle with $(0, 4, 2), (0, 0, c') \in$
Proof: as for Proposition 3 ■

4.3 The $(0,4,1)$ family

Proposition 8 If a right triangle has $V_1 = (0,4,1)$ and tiles the sphere then without loss of generality $V_2 = (0,0,c')$ or $(1,1,c')$.

Proof: as for Proposition 3 ■

Proposition 9 If a right triangle has $V_1 = (0,4,1)$ and $V_2 = (0,0,c')$ and tiles the sphere, then $3c'\geq 6$ and $V = $

\[
\begin{align*}
\{(4,0,0),(0,4,1),(0,0,c'),(1,0,\frac{c'}{2}), (2,0,\frac{c'}{2}), (3,0,\frac{c'}{2})\} & \quad \text{if } c' \equiv 0 \mod 4 \\
\{(4,0,0),(0,4,3),(0,0,c'),(0,1,\frac{3c'+1}{4}), (0,2,\frac{c'+1}{2}), (0,3,\frac{c'+3}{4})\} & \quad \text{if } c' \equiv 1 \mod 4 \\
\{(4,0,0),(0,4,3),(0,0,c'),(1,2,\frac{c'+1}{2}), (2,0,\frac{c'}{2})\} & \quad \text{if } c' \equiv 2 \mod 4 \\
\{(4,0,0),(0,4,3),(0,0,c'),(0,2,\frac{c'+1}{2}), (2,1,\frac{c'+3}{4})\} & \quad \text{if } c' \equiv 3 \mod 4.
\end{align*}
\]

Proof: as for Proposition 4 ■

Proposition 10 No right triangle with $V_1 = (0,4,1)$ and $V_2 = (0,0,c')$ tiles the sphere.

Proof: as for Proposition 5; there is never any second split. ■

Proposition 11 The only right triangle that has $V_1 = (0,4,1)$ and tiles the sphere is the $(90^\circ,75^\circ,60^\circ)$ triangle.

Proof: From Proposition 9 we see that there is no second split unless $c'$ is divisible by 6, in which case we have $(0,0,c')/2$. We also have $(2,0,\frac{c'}{2})/2$ if $12|c'$; there are no other splits. In the case $c' = 6$ we obtain the $(90^\circ,75^\circ,60^\circ)$ triangle; henceforth, then, we suppose $c' \geq 12$. The possible splits are then $(0,0,2m)/2$ with $m \geq 6$ and $(2,0,4n)/2$ with $n \geq 3$.

We see also that $(0,4,1)$ is the only $\beta$ source, so such a vertex must appear in any tiling with this triangle. We examine the neighborhood of any such vertex $O$ (see Figure 14). Let triangle 1 contribute the $\gamma$ angle. Consider the triangle 2, which covers the long leg of 1 near $O$. If the short leg of 2 meets 1 (Figure 14 a and b) and the gap is filled by a right angle, then we need a $\beta$ split, which is impossible. (It is easily checked that $2C \neq B$ for any triangle in this family.)

If the gap is filled by $\gamma$ angles (Figure 14 c), or if the long leg of 1 is covered by the hypotenuse of 2 (Figure 14d), there is a $\gamma$ split at $x$. This split cannot be related in the same way to any other $(0, 4, 1)$ vertex.
Unless the split vertex $X$ is of the form $(2,0,6)/2$ there are more than three \( \gamma \) angles at $X$, and it follows that $O$ and $X$ between them have a surplus of \( \gamma \) angles; thus the entire tiling has a surplus of \( \gamma \) angles, which is impossible.

If $X$ is $(2,0,6)/2$, there must be a right angle at $X$. If $X$ is as shown in Figure 14c, triangles 3 and 4 must be as shown in Figure 15a to avoid a \( \beta \) split; but then whichever way we place the third triangle between them, a \( \beta \) split is required.

If $X$ has the configuration of Figure 14d, and the right angle is between two \( \gamma \) angles (Figure 15b), a \( \beta \) split is required (at $y$); if not (Figure 15c), we must either have a \( \beta \) split at $z$ or $z'$, or have $H + C = 2B$, which is easily shown not to hold for any triangle in this family. We conclude that no other triangle in this family tiles the sphere. 

\[ \]

**4.4 The \((1,3,2)\) family**

**Proposition 12** If a right triangle has $V_1 = (1,3,2)$ and tiles the sphere, then without loss of generality $V_2 = (0,0,c')$, $(0,1,c')$, $(0,2,c')$, or $(1,0,c')$.

Proof: as for Proposition 3.
**Proposition 13** If a right triangle has $V_1 = (1, 3, 2)$ and $V_2 = (0, 0, c')$ and tiles the sphere, then $2|c'$, $c' \geq 8$ and $V$ consists of all vectors in

\[
\{(4, 0, 0), (1, 3, 2), (0, 0, c'), (0, 3, \frac{c' + 8}{4}), (0, 6, \frac{c' - 8}{2}), (1, 0, \frac{3c'}{4}), (2, 0, \frac{c'}{2}), (2, 3, \frac{c' - 8}{4}), (3, 0, \frac{c'}{4})\}
\]

that have nonnegative integer components.

Proof: as for Proposition 4.

**Proposition 14** The only right triangle that has $V_1 = (1, 3, 2)$ and $V_2 = (0, 0, c')$ and tiles the sphere is the $(90^\circ, 60^\circ, 45^\circ)$ triangle, which tiles edge-to-edge.

Proof: As observed above, $c'$ must be even and at least 8. When $c' = 8$ we obtain the known $(90^\circ, 60^\circ, 45^\circ)$ tile, so we consider the case when $c' \geq 10$. The minimum number of $\gamma$ angles at a split other than $(4, 0, 0)/2$ is 3, achieved by the $(2, 0, 6)/2$ split when $c' = 12$.

The only $\beta$ source is the rather weak $(1, 3, 2)$; so such a vertex (call it $O$) must appear in any tiling. Between them, the angles at $O$ have 4 short edges, 3 medium edges, and 5 hypotenuses. There is thus at least one unpaired hypotenuse. This cannot be covered exactly by other edges; $2C < H < B + C$, and in the absence of a $\beta$ split we cannot have more than two short edges on an extended edge. The other end of this hypotenuse is therefore at a split, necessarily involving at least three $\gamma$ angles.

The split vertex is contained in an extended edge which terminates at $O$. At most two $(1, 3, 2)$ vertices can be related to one split in such a way; but between them these three vertices have seven $\gamma$ angles and only six $\beta$ angles. Thus no such tiling is possible.

**Note:** In fact, it is probably true that the split vertex could not be related even to a second $(1, 3, 2)$ vertex, but it is easier to concede the point.

**Proposition 15** No right triangle with $V_1 = (1, 3, 2)$ and $V_2 = (0, 1, c')$ tiles the sphere.

Proof: Calculation shows that $N = 8c' - \frac{46}{3}$, which is never an integer.

**Proposition 16** No right triangle with $V_1 = (1, 3, 2)$ and $V_2 = (0, 2, c')$ tiles the sphere.

(The proof of this proposition is lengthy, and is carried out in the companion paper [6].)

**Proposition 17** The only right triangle with $V_1 = (1, 3, 2)$ and $V_2 = (1, 0, c')$ that tiles the sphere is the $(90^\circ, 60^\circ, 45^\circ)$, already listed in Proposition 20.
Proof: If \( c' \equiv 0 \pmod{3} \) we have \((0,0,\frac{4c'}{3}) \in \mathcal{V} \); by Proposition 14 this gives the \((90^\circ, 60^\circ, 45^\circ)\) tile for \( c' = 6 \) and triangles that do not tile otherwise. If \( c' \equiv 1 \pmod{3} \), we have \((0,2,\frac{2c' + 4}{3}) \in \mathcal{V} \) and by Proposition 22 none of these triangles tile. Finally, if \( c' \equiv 2 \pmod{3} \), \( a \equiv 1 \) and the only split is \((4,0,0)/2\).

\[4.5 \quad \text{The \( (1,3,1) \) family}]

**Proposition 18** If a right triangle has \( V_1 = (1,3,1) \) and tiles the sphere, then without loss of generality \( V_2 = (0,0,c'), (0,2,c'), (1,0,c') \) or \((1,1,c')\).

Proof: as for Proposition 3

**Proposition 19** If a right triangle has \( V_1 = (1,3,1) \) and \( V_2 = (0,0,c') \) and tiles the sphere, then \( 3|c', c' \geq 6 \) and \( \mathcal{V} \) consists of all vectors in

\[\{ (4,0,0), (1,3,1), (0,0,c'), (0,3, c' + \frac{4}{4}), (1,0, \frac{3c'}{4}), (2,0, \frac{c'}{2}), (3,0, \frac{c'}{4}) \}\]

that have integer components.

Proof: as for Proposition 4

**Proposition 20** The only right triangle that has \( V_1 = (1,3,1) \), \( V_2 = (0,0,c') \), and tiles the sphere is the \((90^\circ, 75^\circ, 45^\circ)\) triangle.

Proof: We note that there is no second split when \( c' \) is odd; so by Proposition 1 we may assume \( c' \) to be even. There is never a \( \beta \) split. As a result, there can be no \((1,0,\frac{2c'}{3})\) or \((3,0,\frac{c'}{2})\) vertices. The right angles at such a vertex would have between them an odd number of short edges terminating in \( \beta \) angles, at least one of which would be unmatched. By the same token, a \((2,0,\frac{c'}{2})\) vertex can only exist if \( 4|c' \) and the two short edges of the right triangles are paired, as in Figure 16a.

\[21\]
We will now show that (with this interpretation) a split vertex involving $\gamma$ angles always exists. (Note that Proposition 1 states that a tile other than $(90, 108, 54)$ must have a second split vector, but not that it is necessarily used in the tiling.) Suppose, for a contradiction, that there is a tiling that does not use any $\gamma$ split. As $(0, 3, \frac{c' + 4}{4})$ is never a $\beta$ source, there must exist at least one $(1, 3, 1)$ vertex. In the absence of non-right-angle splits, the only possible configuration at such a vertex is as shown in Figure 16b. But then the edge $\overline{pq}$ must be covered by another medium edge. The right angle cannot go at $B$, as no vertex vector has two right angles and a $\beta$; we thus have the configuration of Figure 16c, in which $q$ is the required $(2, 0, \frac{c'}{2})$ vertex.

However, we will see that unless $n = 8$ no split vertex is possible. It is clear that when we put a “fan” of $\gamma$ angles at a vertex, all $\beta$ angles must either be at the end of the “fan” or paired, as otherwise there will be an overhang and a gap that cannot be filled without a $\beta$ split. (Figure 17a). For a $(0, 0, c')/2$ split, $c' \geq 10$ this results in two pairs of adjacent edges such as $\overline{pq}, \overline{qr}$. In the absence of a $\beta$ split, the only way to cover either of these extended edges is with another pair of triangles as shown; but this leaves an impossible four $\beta$ angles at $B$. Similar problems occur for $(2, 0, \frac{c'}{2})/2$ splits with $c' \geq 20$ (Figure 17b).

There remain three cases when $c' = 6, 12, \text{and} 16$. When $c' = 6$, the only split vector is $(0, 0, 6)/2$. Avoiding overhangs at $\beta$ angles forces the configuration of Figure 18a.

If the extended edge $\overline{pq}$ extended beyond $q$, we would have an overhang or a fourth $\beta$ angle at $r$; neither is permitted. It follows that $\overline{pq}$ is a complete extended edge and must be covered by another hypotenuse and short edge on the other side; this implies a second copy of the same configuration. If the second copy were a mirror image, we would have four $\beta$ angles at $p$; the only alternative is the configuration of Figure 18b. The edge $\overline{qr}$ must be matched, but we cannot have two right angles and a $\beta$ together, so the triangle 1 (and the corresponding 1') must be as shown. This leaves a $\gamma$ gap at $r$ which must be filled by triangle 2 as shown, putting a $\beta$ angle at $s$. But then the edge $ps$ cannot be covered without creating an illegal combination of angles at one end or the other.

When $c' = 12$ we have already ruled out $(0, 0, 12)/2$ but we must show that the $(2, 0, 6)/2$ split also leads to illegal configurations. By arguments similar to
those used in the last case, we obtain the configuration of Figure 19a. If we put a right angle and a γ angle into the gap at p, the short edge at the right angle will be unpaired and will require an illegal β split; it follows that p must be a (0, 3, 4) vertex.

There are only two ways to place the γ angles without a β split; in Figure 19b, an overhang is created that makes it impossible to cover the remaining edge of triangle 1, while in Figure 19c, we eventually get four β angles at q (as in Figure 17).

Finally, when $c' = 16$, we first note that we cannot have a (0, 3, 5) vertex. The set of edges of the angles meeting at such a vertex would contain eight hypotenuses, five of them from γ angles and hence terminating in a β angle. All of these must be paired with other hypotenuses to prevent a β split, and at least two of them must be paired with each other, as triangles 1, 2 are in Figure 20a.

We now examine the medium edges of these angles. Either one of these edges is matched (as at left), in which case there is an extended edge $pq$ which must be matched exactly by two more short edges; or it is not, in which case there is an overhang (as at r). In any case, we end up with two more β angles at p, which is impossible.

Now we show that we cannot have a (2, 0, 8)/2 split. Suppose we did; by arguments similar to those used above, its neighborhood would have the config-

Figure 18: The (0, 0, 6)/2 split

Figure 19: The (2, 0, 6)/2 split
uration of Figure 20b. The extended edge $\overline{st}$ must be covered as shown (triangles 3,4 in Figure 20c). Triangle 5 is then forced, as the only way to cover $\overline{tu}$ without creating a $\beta$ split.

![Figure 20: The (2,0,8)/2 split](image)

Then $t$ must be a $(1,3,1)$ vertex. The remaining $\gamma$ angle is provided by triangle 6. The hypotenuse of that triangle must be paired with that of triangle 4 to avoid a $\beta$ split; but then vertex $v$ has at least two $\gamma$ angles and a $\beta$ angle. However, the only such vertex vector is $(0,3,5)$, and we have seen that this cannot occur in a tiling.

![Figure 21: The (1,3,1) vertex in the absence of the (2,0,8)/2 split](image)

But if we have no split in the tiling except for $(4,0,0)/2$, it is easily seen that every $(1,3,1)$ vertex must have the configuration of Figure 21a. The extended edge $\overline{xy}$ must be covered exactly, and this can only be done as shown in Figure 21b. But then vertex $x$ has two $\gamma$ angles and a $\beta$ angle, and we have seen that this is impossible. We conclude that this triangle fails to tile the sphere. ■

**Proposition 21** If a right triangle has $V_1 = (1,3,1)$ and $V_2 = (0,2,c')$ and tiles the sphere, then $c' \geq 4$ and $\mathcal{V}$ consists of all vectors in

$$\{(4,0,0),(1,3,1),(0,2,c'),(0,5,\frac{4-c'}{2}),(1,0,\frac{3c'-2}{2}),(2,1,\frac{c'}{2})\}$$

that have positive integer components.

Proof: as for Proposition 4 ■
Proposition 22 The only right triangles that have \( V_1 = (1, 3, 1), \) \( V_2 = (0, 2, c'), \) and tile the sphere are the \((90^\circ, 72^\circ, 54^\circ)\) triangle and the \((90^\circ, 78\frac{3}{4}^\circ, 33\frac{3}{4}^\circ)\) triangle.

Proof: From the previous proposition, \( c' \) must be even and greater than or equal to 4. When \( c' = 4 \) we get the \((90^\circ, 72^\circ, 54^\circ)\) triangle, which is a quarterlune (although, atypically, it has \( \theta > 180^\circ - 2\theta \), so its polar angle is \( \beta \) and not \( \gamma \).) For \( c' = 6 \) we get the \((90^\circ, 78\frac{3}{4}^\circ, 33\frac{3}{4}^\circ)\) triangle. This tiles the sphere with \( N = 32 \).

We will now show that when \( c' \geq 8 \) the \((0, 2, c')/2\) split is not realizable. Firstly, if there is such a split, then without loss of generality there exists one with the short edge of the \( \beta \) angle on the extended edge containing the split, as in Figure 22a; for if it is located as in Figure 22b,c, then there is, as shown, another split of the required form nearby, at the point marked \( x \). (Note that for \( c' \geq 8 \) both the medium edge and hypotenuse are more than twice as long as the short edge, and that in every case the only split involving right angles is \((4, 0, 0)/2\).)

![Figure 22: A default form for the \((0, 2, c')/2\) split](image)

We will now show by induction that all the edges in the fan of \( \gamma \) angles are matched. Consider the \( \gamma \) angle adjacent to the \( \beta \) angle. If this is positioned as Triangle 2 in Figure 23a,b, a right-angled split is created. If this were filled as in Figure 23a, then either way of covering the hypotenuse of triangle 2 would require a split with two \( \beta \) angles. The only alternative, in Figure 23b, forces the hypotenuse of triangle 2 to be matched by triangle 3, as shown. There cannot be a fourth \( \beta \) angle at \( p \); we thus have either a \( \gamma \) angle (not shown) or a right angle next to triangle 3 at \( p \). Any choice of angle and orientation forces triangle 5 as shown, and the overhang at \( q \), which makes it impossible to cover the hypotenuse of triangle 5. (As \( c' > 6 \), this hypotenuse is not the other side of the split.)

We thus have Triangle 2 positioned as shown in Figure 23c. If the medium leg of triangle 2 were not matched, we would have a an overhang at \( r \), forcing the \( \gamma \) angle of triangle 4. Triangle 5, with its uncoverable hypotenuse, again follows. Thus, the medium edges must match (Figure 23d).

Again, the hypotenuses of the third and fourth triangles in the split must match. Suppose not; if the short edge of triangle 4 is not matched, its hypotenuse cannot be covered (figure 24a). If it is matched (triangle 5 in figure 24b), triangles 6 and 7, the \( \gamma \) angle 8, and triangle 9 are forced in that order. However,
Figure 23: A default form for the \((0, 2, c')/2\) split: the second and third triangles

this creates an impossible combination of angles at \(v\). We conclude that the first four angles of the fan must be as in figure 24c.

Figure 24: The fourth triangle

We can now proceed inductively to show that the other edges in the split are also matched. Suppose, for a contradiction, that the first unmatched edge to be between triangles numbered \(2^n + 1\) and \(2^n + 2\), \(n \geq 2\), as in Figure 25a. The overhang and split at \(x\) and the gamma angle labelled 1 are forced, resulting in an impossible configuration at \(y\). If, on the other hand, the first unmatched edge is between triangles \(2n\) and \(2n + 1\), triangle 1 of Figure 25a is forced; we then get the overhang and split at \(z\), triangle 2, the \(\gamma\) angle 3, and triangle 4. However, the hypotenuse of triangle 4 cannot be covered. It follows, then, that all the edges between the angles at an \((0, 2, c')/2\) split with the \(\beta\) angle as shown are matched.

The next step is to show that in fact no split configuration of this type (and hence no \((0, 2, c')/2\) split whatsoever) exists in a tiling of the sphere. If \(c'/2\) is even, we have a configuration something like Figure 26a. There cannot be an overhang at \(p\), because the new split would require a triangle (as shown), which would prevent the original vertex from being a split as hypothesized. It follows that the extended edge \(\overline{pq}\) is covered by the short edges of two more triangles, necessarily positioned as shown in Figure 26b.
If \( c' \geq 12 \) the next two short edges must be covered in the same way and we immediately have an impossible four \( \beta \) angles at \( q \). If \( c' = 8 \) we can avoid this only by having an overhang and split at \( r \). Completing this split gives us Figure 26c; but there is no way to cover the extended edge \( \overline{w'z} \) without an illegal split or a fourth \( \beta \) at \( q \). We conclude that there is no \((0, 2, c')/2\) split when \( c'/2 \) is even.

When \( c'/2 \) is odd, we have a configuration like that of Figure 26a. Again, if \( c' \geq 14 \) we immediately get a vertex with four \( \beta \) angles and we are done. When \( c' = 10 \), we can have a \((1, 3, 1)\) vertex at \( y \) and an overhang and split at \( z \) (Figure 26b); but any way of putting a right angle or a \( \gamma \) angle along \( \overline{yw'} \) creates an impossible configuration.

A right angle with the short edge on \( \overline{yw'} \) gives the configuration of Figure 26c; the split at \( p \) must have triangles 2 and 3 as shown, and any attempt to fill the right angle gap at \( q \) created an illegal overhang at either \( r \) or \( w' \). On the other hand, if triangle 1 is placed with its right angle at \( y \) and its long edge along \( \overline{yw'} \), there must be an overhang at \( s \) and its hypotenuse can only be covered as shown. After triangle 2 is placed, the remaining angles at the split at \( t \) are all \( \gamma \) angles, forcing angle 3 as shown; triangle 4 is then forced, and its hypotenuse cannot be covered.

The two cases with \( \gamma \) angles on \( \overline{yw'} \) are ruled out by similar arguments. We conclude that for \( c' > 6 \) no \((0, 2, c')\) split can be realized. From this it is straightforward to rule out all \( \gamma \) sources, and thus to show that tiling is impossible.

**Proposition 23** The only right triangles that have \( V_1 = (1, 3, 1), V_2 = (1, 0, c') \),
and tile the sphere are those listed in Propositions 20 and 22.

Proof: If \( c' \equiv 0 \pmod{3} \), then \((0, 0, \frac{4c' + 1}{3}) \in V \). This gives the \((90^\circ, 75^\circ, 45^\circ)\) tile for \( c' = 6 \) and Proposition 20 shows that the triangle does not tile otherwise. If \( c' \equiv 2 \pmod{3} \), then \((0, 2, 2\cdot\frac{c' + 1}{3}) \in V \); we get the \((90^\circ, 72^\circ, 54^\circ)\) tile for \( c' = 5 \), the \((90^\circ, 78^\circ, 33^\circ)\) for \( c' = 8 \), and (by Proposition 22) a triangle that does not tile for all other \( c' \). Finally, if \( c' \equiv 1 \pmod{3} \), following the methods of Proposition 4 we find that \( a \equiv 1 \) as well, yielding no split except \((4, 0, 0)\). \( \blacksquare \)

Proposition 24  No right triangle with \( V_1 = (1, 3, 1) \) and \( V_2 = (1, 1, c') \) tiles the sphere.

Proof: Again, every element of \( V \) has \( a \equiv 1 \pmod{3} \), so that the only split is \((4, 0, 0)\). \( \blacksquare \)

5 Other results

Proposition 25  The tiling shown in Figure 4 is (up to reflection) the only tiling of the sphere with the \((90^\circ, 75^\circ, 60^\circ)\) triangle.

Proof: Calculation shows that \( V_T = \{(4,0,0), (2,0,3), (1,2,2), (0,4,1), (0,0,6)\} \); as observed above, there is no \( \beta \) split, so there cannot be an overhang on either side of a \( \beta \) angle. We look at possible covers for the short leg \( \overline{pq} \) of a triangle.

If \( \overline{pq} \) is covered by a longer edge, there is an overhang as shown in Figure 28. The gap at \( p \) must be filled by a right angle, in one of two positions. As
Figure 28: An impossible configuration

\( H/C = 1.378 \ldots \) and \( B/C = 1.234 \ldots \), either of these must result in a \( \beta \) split at \( x \), which is not possible.

If \( pq \) is covered by another short leg with the opposite orientation (Figure 29), the edge \( pr \) cannot extend past \( r \). Suppose, for the sake of contradiction, that it did; triangle 1 would be forced. The remaining angles at \( q \) would be \( \gamma \)'s, forcing an overhang at \( s \), so that triangle 2 must be as shown. There cannot be an overhang at \( t \), and the extended edge \( qt \) must be covered by two more long legs, as no other combination of edges equals \( 2B \). However, \( q \) already has two \( \beta \) angles and a right angle, and cannot accept another of either type.

Figure 29: Another impossible configuration

Thus, if \( pq \) is covered as shown, \( pr \) must be covered by another edge of the same length; as there cannot be another right angle at \( p \), we have the configuration of Figure 30a. The angle \( \angle upv \) must be filled with no overhang at \( u \) or \( v \); this forces (essentially) the configuration of Figure 30b, and, as in Figure 28, filling the 90° gap at \( x \) will force a \( \beta \) split.

Figure 30: A third impossible configuration

We conclude that \( pq \) is paired with another short leg, oriented in the same way. It follows that the triangles in the tiling are partitioned into mirror-image pairs, forming \((150°, 60°, 60°)\) triangles; as shown in [3], these tile the sphere
6 Conclusion

This paper lists all the asymptotically right right triangles that tile the sphere, including one infinite family, and four sporadic triangles, that tile only in a non-normal fashion. It is part of a sequence of papers (along with [7] and [8]) that will give a complete classification of the right triangles that tile the sphere.
